22 **Running title:** Red algae with wide geographical distributions

23 ABSTRACT

24 Despite studies suggesting that most seaweeds are poor dispersers, many red algal
 25 species are reported to have circumglobal distributions. Such distributions have mostly
 26 been based on morphological identifications, but molecular data have revealed a range
 27 of issues with morphologically defined species boundaries. Consequently, the real
 28 distribution of such reportedly circumglobal species must be questioned. In this study,
 29 we analysed molecular datasets (*rbcL* gene) of nine species in the Rhodomelaceae for
 30 which samples were available from widely spaced geographical locations. Three overall
 31 patterns were identified: 1) species showing strong phylogeographic structure (i.e.
 32 phylogenetic ~~structure-similarity~~ correlates with geographical provenance), often to the
 33 point that populations from different locations could be considered as different species
 34 (*Lophosiphonia obscura*, *Ophidocladus simpliciusculus*, *Polysiphonia villum* and
 35 *Xiphosiphonia pinnulata*); 2) ~~3) species with a broad distribution that is explained, in~~
 36 ~~part, by putative human-mediated transport (*Symphyocladia dendroidea* and-~~
 37 ~~*Polysiphonia devoniensis*); and 3) non-monophyletic complexes of cryptic species,~~
 38 most with a more restricted distribution than previously thought (*Herposiphonia tenella*,
 39 *Symphyocladia dendroidea* and the *X. pennata* complex that includes the species *X.*
 40 *pinnulata* and *S. spinifera*); ~~3) species with a broad distribution that is explained, in part,~~
 41 ~~by putative human-mediated transport (*S. dendroidea* and *P. devoniensis*).~~ This study
 42 shows that widely distributed species are the exception in marine red algae, unless they
 43 have been spread by humans.

44

45 *Key words:* introductions, new record, phylogeography, Rhodomelaceae,
 46 Polysiphonieae, Pterosiphonieae, Herposiphonieae, *rbcL*, species boundaries, species
 47 complexes

48 INTRODUCTION

49 Phylogeography of marine organisms is influenced by barriers to dispersal and
50 geographical distance, as well as by aspects of their life-history, physiology and ecology
51 (Jackson 1974, Palumbi 1994, Riginos et al. 2011). The dispersal ability of seaweeds is
52 generally very limited, of the order of tens of meters or less (Santelices 1990, Kinlan
53 and Gaines 2003, Destombe et al. 2009). However, long-distance dispersal is known in
54 brown seaweeds with buoyant structures (Fraser et al. 2009, Macaya and Zuccarello
55 2010), which can act as rafts promoting in turn the dispersal of the epiphytic species
56 that they host ([Fraser et al. 2013](#), Macaya et al. 2016, López et al. 2017, 2018). Still, a
57 large proportion of macroalgae are epilithic, so their expected dispersal ability is very
58 limited and consequently their distribution range is expected to be relatively small.
59 Paradoxically, many macroalgal species are reported to be very widely or even globally
60 distributed.

61 Records are usually based only on morphological identification, which can be
62 inaccurate due to morphological plasticity within species as well as similarity between
63 cryptic species (e.g. Verbruggen 2014, Schneider et al. 2017). Closer investigation of
64 material from distant regions using DNA data commonly leads to the discovery of
65 cryptic species (e.g. Won et al. 2009, Bustamante et al. 2014, Schneider et al. 2017).
66 Even though studies combining morphological and molecular data are increasing, DNA
67 databases are still very limited for most algal groups and molecular data are often
68 available only for some regions. As a consequence, the true distribution of many
69 seaweed species should be regarded as uncertain. Few studies have reassessed the
70 distribution of widely reported red algal species using molecular data from a broad
71 sampling area. -Complexes of look-alike species, as well as widely distributed species,
72 have been detected (Zuccarello et al. 1999, Zuccarello et al. 2002a, Zuccarello & West

2003, Won et al. 2009). Among the widely distributed species, some exhibit high genetic variability and strong phylogeographic structure that often distinguishes populations from different basins (Zuccarello et al. 2002a, b, Won et al. 2009). Other widely distributed species lack phylogeographic signal, suggesting long-distance dispersal processes by unknown mechanisms (Zuccarello et al. 2002a, Fraser et al. 2013). Therefore, red algal phylogeographic patterns are highly heterogeneous and depend on evolutionary histories and dispersal abilities.

In addition to natural dispersal mechanisms, human-mediated vectors can transport seaweeds from native areas to other world regions and rapidly alter distribution patterns (Straub et al. 2016). More than 208 red algal species have been considered as introduced or cryptogenic in one or several regions (Thomsen et al. 2016). Cryptic introductions are common in the red algae and non-native species often remain unnoticed until diversity surveys use molecular tools (McIvor et al. 2001, Zuccarello et al. 2002b, Díaz-Tapia et al. 2013b, 2017a). Considering the low dispersal ability of non-buoyant epilithic red algae, we hypothesize that the distribution of most truly cosmopolitan species can be explained by human-mediated transport – which is frequently provided as a potential explanation for wide distributions of species (Zuccarello et al. 2002a,b, Fraser et al. 2013).

The Rhodomelaceae, with >1,000 recognized species, is the most diverse red algal family (Guiry and Guiry 2018). It includes numerous examples of widely reported species and, as in most red algal groups, cryptic diversity is common (e.g. Zuccarello et al. 2002a, Díaz-Tapia and Bárbara 2013, Bustamante et al. 2014, Savoie and Saunders 2016, Zuccarello et al. 2018). Furthermore, among the red algae the Rhodomelaceae accounts for the largest number of introduced species (Williams and Smith 2007). Members of this family are often major components of algal turfs where canopy-

98 forming brown algae with buoyant structures are rare as a consequence of the stressful
99 conditions imposed by the presence of sediment (Airoldi 1998, Díaz-Tapia et al. 2013a).
100 This makes the family a good candidate to test hypotheses about species distributions
101 and phylogeographic patterns.

102 The objective of this paper is to reassess the wide reported distributions of nine turf-
103 forming species of the family Rhodomelaceae using DNA sequences. Using molecular
104 data from distant locations within each species' reported distribution range, we evaluate
105 whether these are indeed widely distributed species, analyse the observed
106 phylogeographic patterns, and consider whether these species may have been introduced
107 into one or several regions by human activities.

108

109 MATERIALS AND METHODS

110 Material of *Herposiphonia tenella*, *Lophosiphonia obscura*, *Ophidocladus*
111 *simpliciusculus*, *Polysiphonia villum*, *P. devoniensis*, *Symphyocladia spinifera*, *S.*
112 *dendroidea*, *Xiphosiphonia pennata* and *X. pinnulata* was collected in Norway, United
113 Kingdom, France, Spain, Portugal, Italy, Brazil, Chile, Australia and South Africa
114 during general sampling surveys of the family Rhodomelaceae (Table S1). All these
115 species form epilithic turfs, most of them on intertidal sand-covered rocks (Womersley
116 2003, Díaz-Tapia & Bárbara 2013). *Lophosiphonia obscura* was found in North
117 Atlantic brackish water coastal lagoons or estuaries, and *Symphyocladia dendroidea*
118 was collected in Australian and Chilean shallow subtidal turfs. Distribution maps of
119 records for these species (Figs 1-3, lines) were drawn up based on information available
120 in AlgaeBase [and references therein](#) (Guiry and Guiry 2018).

121 DNA was extracted from silica gel-dried material following Saunders and McDevit
 122 (2012), using the Qiagen DNeasy Plant Mini Kit (Qiagen GmbH, Hilden, Germany) or
 123 the Promega Wizard Magnetic 96 DNA Plant System kit (Promega Corporation,
 124 Madison, USA), following the manufacturer's instructions. PCR amplification was
 125 carried out for the *rbcL* gene using primers F7/RrbcStart, F7/R893 or F57/rbcLrevNEW
 126 (Freshwater and Rueness 1994, Mamoozadeh and Freshwater 2011, Saunders and
 127 Moore 2013), as well as the newly designed primers F2
 128 (TGTCTAACTCTGTAGAACAACGGA), F8 (ACTCTGTAGAASAACGGACAMG),
 129 R1008 (AACTACTACAGTACCAGCATG), R1464
 130 (AACATTAGCTGTTGGAGTTTCYAC) and R1452
 131 (TGGAGTTTCYACRAAGTCAGCTGT). [Names of these primers indicate their](#)
 132 [position in the *rbcL* gene \(e.g. first base of F2 primer corresponds with the second base](#)
 133 [of the *rbcL* gene\).](#) PCR reactions were performed in a total volume of 25 μ l; ~~consisting~~
 134 ~~containing of 5 μ l 5 \times MyTaqTM reaction buffer, 0.7 μ l 100.28 μ M of forward and~~
 135 reverse primers, 0.125 ~~μ l 1U/ μ units~~ My TaqTM DNA Polymerase (Bioline, London,
 136 UK), ~~17.475 μ l MilliQ® water~~ and 1 μ l template DNA. The PCR profile consisted of
 137 initial denaturation (93°C for 3 min), 35 cycles of denaturation (94°C for 30 s), primer
 138 annealing (45°C for 30 s), and extension (74°C for 90 s) and final extension (74°C for 5
 139 min). The PCR products were purified and sequenced at Queen's University of Belfast
 140 on an AB3730xl DNA Analyzer (Applied Biosystems, Foster City, CA, USA) or
 141 commercially by Macrogen or the sequencing service of the University of A Coruña.

142 A total of 128 new *rbcL* sequences were generated in this study and an additional
 143 91 sequences were downloaded from GenBank (Table S1). Length of sequences ranged
 144 from 585 to 1467 (Table S1). Sequences were aligned using Muscle in Geneious 6.1.8
 145 (Kearse et al. 2012). As a first stage, we analysed these sequences in taxon-rich datasets

146 for the tribes Herposiphoniae, Pterosiphoniae, Polysiphoniae and Streblocladiae to
147 verify that the target species were monophyletic. Based on the resulting trees, we
148 selected all sequences corresponding to the species (or group of closely related species)
149 that are the focus of this paper. These datasets were analyzed species by species using
150 the unweighted pair group method with arithmetic mean (UPGMA). For two complexes
151 of ~~unrelated non-sister~~ species in our initial taxon-rich trees (*Symphycladia dendroidea*
152 and *Herposiphonia tenella*), we included wider species sampling considering the
153 available data for the respective genera (Table S1). We performed maximum likelihood
154 (ML) analyses separately for each of the two genera using RAxML 8.1.X (Stamatakis
155 2014). GTR-Gamma was used as the nucleotide model and branch support was
156 estimated with 1000 bootstrap replicates. Three species of *Xiphosiphonia* and
157 *Dipterosiphonia* were selected as the respective outgroups for the *Symphycladia* and
158 *Herposiphonia* trees based on our phylogenomic analyses of the major lineages of the
159 Rhodomelaceae (Díaz-Tapia et al. 2017b).

160

161 RESULTS

162 The taxonomy of several of the studied species is complex and details are provided in
163 Supplement 1.

164 *Ophidocladus simpliciusculus*

165 *Ophidocladus simpliciusculus* was collected in four out of the six world regions where it
166 has been reported (Fig. 1a). ~~In Australia, its previously known distribution included~~
167 ~~South and Western Australia and our collections from Tasmania and Victoria (Table~~
168 ~~S1) are new records for these states.~~ The UPGMA analyses included 15 newly
169 determined *rbcL* sequences and two downloaded from GenBank (Table S1). Sequences
170 comprised four haplotypes (Fig. 1b): haplotype 1, seven samples from Europe (Atlantic

171 and Mediterranean); haplotype 2, six samples from Australia; haplotype 3, one sample
 172 from South Africa; and haplotype 4, three samples from Brazil. The South African
 173 sample differed by only 0.1% (1 bp) from the Australian samples, while Brazilian
 174 samples were the most divergent (up to 0.8% and 11 bp) from samples from other
 175 regions. Our results indicate that *O. simpliciusculus* has a unique *rbcL* haplotype in each
 176 region, but it has a strong phylogeographic structure.

177

178 *Lophosiphonia obscura*

179 *Lophosiphonia obscura* has been reported in the Atlantic and Indo-Pacific and
 180 sequences are available from Europe and Australia (Fig. 1c). ~~In Australia, it had been~~
 181 ~~previously recorded only in Southern Australia and our collection from Victoria is a~~
 182 ~~new record for this state.~~ Furthermore, our dataset also included *Polysiphonia*
 183 *hemisphaerica* from Norway and *P. boldii* from Texas, USA ~~which may be conspecific~~
 184 ~~as suggested by the low *rbcL* divergence with *L. obscura*~~ (see Supplement 1). We
 185 analysed six newly determined *rbcL* sequences and two downloaded from GenBank for
 186 *Lophosiphonia obscura*, *Polysiphonia hemisphaerica* and *P. boldii* (Table S1). Four
 187 haplotypes were found (Fig. 1d): 1) four samples from Spain (Atlantic and
 188 Mediterranean) and Norway; 2) a sample from the United Kingdom; 3) a sample from
 189 USA; and 4) two samples from Australia. Atlantic samples differed by 0.1-0.2% (1-2
 190 bp), while Australian samples were 0.7-0.9% (8-11) divergent from the Atlantic
 191 samples. Our results indicate that the lineage formed by these three taxa is moderately
 192 variable in the North Atlantic, and is clearly separated from the Australian
 193 ~~haplotype populations.~~

194

195 *Polysiphonia villum*

196 Molecular data were obtained from two regions where *Polysiphonia villum* (as *P.*
197 *scopulorum* var. *villum*, see Supplement 1) had previously been reported (Fig. 1e).
198 Furthermore, it was also sampled in Spain, the French Mediterranean and Australia,
199 where it is here newly recorded. The 13 sequences determined for *P. villum* and the two
200 downloaded from GenBank (Table S1) belong to three haplotypes (Fig. 1f): 1) four
201 samples from Australia, 2) three samples from Brazil and 3) eight samples from the
202 North Atlantic (North Carolina, Spain and France). Australian samples were 0.5-0.6%
203 (4-7 bp) divergent from the Atlantic samples and the Brazilian sequences differed by
204 0.2% (2 bp) from the North Atlantic samples. Thus, *P. villum* shows a clear
205 phylogeographic structure.

206

207 *Polysiphonia devoniensis*

208 Our dataset included samples from the previously recorded distribution in Atlantic
209 Europe, as well as from the northwestern Mediterranean (Italy and France), the Adriatic
210 Sea (Italy) and Victoria (Australia), from where *P. devoniensis* is here recorded for the
211 first time (Fig. 2a, Table S1). Furthermore, sequences of *P. kapraunii* from North
212 Carolina were also included in our dataset (see Supplement 1). Analyses including an
213 *rbcL* sequence of *P. kapraunii* from GenBank and 21 newly determined sequences of *P.*
214 *devoniensis* (Table S1) showed eight haplotypes (Fig. 2b). One haplotype was found in
215 the northwestern Mediterranean, Atlantic Spain and Australia; one occurred in the
216 Adriatic Sea and the northwestern Mediterranean; and six haplotypes were each
217 represented by a single sample (two from Wales, two from the Adriatic Sea, one from
218 the northwestern Mediterranean and one from North Carolina). The North Carolina

sample identified as *P. kapraunii* was 0.2-0.3% (3-4 bp) divergent from two of the European samples (PD301 and PD2430). These three samples differ from the others by sequence divergences of 1-1.4% (12-18 bp), while divergence between the other five haplotypes is 0.1-1% (1-9 bp). The lineage formed by samples assigned to *P. devoniensis* and *P. kapraunii* has a high genetic diversity and the distribution of haplotypes lacks geographic structure. ~~The discovery of *P. devoniensis* in Victoria (Australia), exhibiting a single haplotype that is also present in Europe, suggests that this species has been introduced into this country from Europe, possibly Atlantic Spain or the NW Mediterranean.~~

Symphyocladia dendroidea complex

Sequences of *Symphyocladia dendroidea* are available from most of the previously known distribution (British Columbia, California, Chile, Peru, Japan and the Mediterranean). Some of these sequences were labelled as *Pterosiphonia tanakae* (see Supplement 1). Furthermore, we collected this species in a Galician marina (northwestern Spain) and in Australia (Victoria), where it is here recorded for the first time (Fig. 2c).

The *rbcL* data for *Symphyocladia dendroidea* reveal cryptic diversity in the Americas, as specimens from Peru and Chile and specimens from British Columbia (here referred as *S. dendroidea* 2) do not constitute a clade (Fig. S1, Table S1). In addition to these regions, both were recorded in California. *S. dendroidea* is resolved as sister to *S. parasitica* with high support, while *S. dendroidea* 2 is placed in a moderately supported clade together with *S. brevicaulis* and *S. baileyi* (Fig. S1). Molecular data show that *S. dendroidea* has a wide distribution in the Pacific and occurs in some

243 European locations, while *S. dendroidea* 2 is apparently restricted to Pacific North
 244 America.

245 In total, 28 *rbcL* sequences were analysed for *Symphocladia dendroidea* (some
 246 sequences labelled as *S. tanakae*, see Supplement 1) including 13 newly determined and
 247 15 downloaded from GenBank (Table S1). The UPGMA dendrogram shows seven
 248 haplotypes (Fig. 2d) of which five comprise samples from Pacific South America, one
 249 includes samples from Australia and Japan, and the other consists of samples from
 250 California and Europe. Maximum variability between South American haplotypes is
 251 0.6% (8 bp), and sequence divergence between them and the two other clades is 0.4-1%
 252 (3-9 bp). These levels of *rbcL* variation suggest that this entity may consist of multiple
 253 species or highly differentiated populations.

254 ~~*Symphocladia dendroidea* was recorded as an introduced species in the French~~
 255 ~~Mediterranean in 2005 (as *P. tanakae*) and our recent discovery of the same haplotype~~
 256 ~~in a marina in Atlantic Spain probably represents a secondary introduction and suggests~~
 257 ~~that the species is spreading in Europe via hull fouling. The presence of several~~
 258 ~~genetically separated lineages in Pacific South America contrasts with the occurrence of~~
 259 ~~a single haplotype in Japan, Australia and California. Furthermore, Japan and Australia~~
 260 ~~have the same haplotype, suggesting that one or both populations could be introduced.~~

261
 262 *Xiphosiphonia pennata* complex, including *X. pinnulata* and *Symphocladia spinifera*
 263 *Xiphosiphonia pennata* has been reported in the Atlantic and Indo-Pacific (Fig 2e) and
 264 this morphological species is a complex of at least three unrelated non-sister species.
 265 Their taxonomy has been resolved with the clarification of the identity of including *X.*

266 | *pinnulata* and *S. spinifera* [that have been misidentified as *X. pennata*](#) (see Supplement
267 | 1).

268 | At present, 39 *rbcL* sequences (16 newly determined and 23 downloaded from
269 | GenBank) are available for *Symphyccladia spinifera* from California, Pacific South
270 | America, Australia and Korea (Fig. 2f). The UPGMA shows 10 haplotypes of which
271 | four correspond to Korean samples, four to Peruvian samples, one to Australian samples
272 | and one to a Washingtonian sample (Fig. 2f). Sequence divergence among haplotypes is
273 | up to 0.9% (7 bp). Australian samples match the morphological concept of
274 | *Xiphosiphonia pennata*, but our molecular data reveal that none of them grouped with
275 | the European *X. pennata* but instead are mostly closely related to *S. spinifera*.
276 | Therefore, *X. pennata* should be excluded from the recorded Australian flora and
277 | replaced by *S. spinifera*. Interestingly, all the Australian samples belong to a single
278 | haplotype, which contrasts with the four haplotypes found in both Peru and Korea.

279 | *Xiphosiphonia pinnulata* sequences were resolved as three haplotypes of which
280 | two were found in European samples and one in Brazilian samples (Fig. 2g). Sequence
281 | divergence among them is up to 0.7% (9 bp) and between the two European clades is up
282 | to 0.3% (3 bp). *X. pennata* was only found in the Atlantic Iberian Peninsula. Therefore,
283 | the widely reported *X. pennata* (as *Pterosiphonia pennata*) is apparently restricted to
284 | European shores. *X. pinnulata* is restricted to the Atlantic, where it has a strong
285 | phylogeographic structure with divergences that may even suggest they are separate
286 | species. *S. spinifera* is restricted to the Pacific and it has a high genetic variability
287 | between regions and within regions in Korea and South America.

288 |

289 | *Herposiphonia tenella* complex

290 In total, 27 *rbcL* sequences were obtained for samples morphologically identified as
 291 *Herposiphonia tenella* from Europe, North America and Queensland (Australia) (Fig.
 292 3). They were analysed together with the available *rbcL* data for the genus (15 species).
 293 The phylogeny ~~(Fig. 4)~~ resolved *H. tenella* in seven ~~clades~~lineages, four from the
 294 Atlantic and three from Queensland (Fig. 4). Sequence divergence among the lineages
 295 was at least 1.9%, while divergence within them was up to 0.7%. Only two of these
 296 ~~clades~~lineages were resolved as sisters (1.9-2.1% sequence divergence), while the
 297 others, despite morphological similarities, were more closely related to other
 298 ~~clades~~lineages. Thus, *Herposiphonia tenella* is a large species complex that requires
 299 taxonomic revision to better understand its cryptic diversity and the distribution of the
 300 resulting new species. Its type locality is in the Mediterranean, where three of the four
 301 European specieslineages were collected.

303 DISCUSSION

304 *Species complexes*

305 In this work we ~~distinguish between~~detected several complexes of non-sister species
 306 (*Xiphosiphonia pennata*, *Symphyocladia dendroidea* and *Herposiphonia tenella*); Also,
 307 we found ~~and~~ species-level taxa that represent monophyletic lineages containing several
 308 haplotypes that in most cases are distributed in accordance with geographical ~~patterns~~
 309 regions. ~~The second group~~They could also be classified as species complexes, as
 310 sequence divergences between haplotypes are often large (up to 1.4%), possible
 311 evidence for multiple species. Interpretations of genetic divergences when delineating
 312 species boundaries vary among authors. For example, *Melanothamnus*
 313 *harveyi/japonicus* and other closely related species have been interpreted as a single

species [with an intraspecific variability in the *rbcL* gene \$\leq 2.1\$ %](#) (McIvor et al. 2001, as
Polysiphonia) or as a species complex [in which interspecific variability in the *rbcL* gene](#)
[is 0.3-0.7 %](#) (Savoie and Saunders 2015, as *Neosiphonia*). The species concept has been
 hotly debated, but there is a general consensus that speciation is a process that takes
 place when gene flow is interrupted as a consequence of isolation of populations (Coyne
 et al. 1988, Leliaert et al. 2014). In the present work, assessing species boundaries was
 not always straightforward, and we used information based on genetic divergences,
 species distribution and, in one lineage, interbreeding experiments [described by](#)
[Rueness \(1973\)](#). The first scenario we encountered consists of species with a variety of
 haplotypes [separated by large geographical distances found in distant locations](#). Genetic
 isolation by distance seems obvious considering our data and, in some cases, where the
 divergences between distant populations are [particularly relatively](#) large (~~\leq up to~~ 0.9%),
 one might consider them different species (*Ophidocladus simpliciusculus* from Europe
 vs. Brazil vs. Australia/South Africa, *Lophosiphonia obscura* from the North Atlantic
 vs. Australia, *Polysiphonia villum* from the Atlantic vs. Australia, and *Xiphosiphonia*
pinnulata from Brazil vs. Europe). However, the low number of samples in some
 regions or species, as well as the lack of sampling in other regions where these species
 were recorded or may be still unknown precludes a definitive conclusion. Perhaps the
 observed large sequence divergences between the lineages within these species would
 be less evident with larger datasets. A second scenario is similar to the former, as it
 consists of species with a variety of haplotypes, but in this case several haplotypes share
 the same distribution (*P. devoniensis*, *Symphyocladia dendroidea*, *S. spinifera*). Thus,
 despite *rbcL* divergences among some haplotypes (~~\leq up to~~ 1.4%) being even larger than
 in the previous group (~~\leq up to~~ 0.9%), whether they are at present reproductively isolated
 and should be considered as distinct species is uncertain. Interbreeding experiments

339 may assist to clarify if these species should be considered as distinct or not. While
 340 successful reproduction may have multiple interpretations (Leliaert et al. 2014),
 341 unsuccessful reproduction indicates reproductive incompatibility. The third scenario we
 342 found in this work is represented by *Lophosiphonia obscura* whose eastern and western
 343 Atlantic populations have low genetic distances (0.1-0.2 %) in the *rbcL* gene, and also
 344 in the more variable *cox1* marker (0.6-1.2 %, HQ412544-5 as *P. hemisphaerica* and *P.*
 345 *boldii*, MF094025). Despite this, crossing experiments demonstrate that isolates from
 346 Texas and from Norway fail to produce fully fertile progeny (Rueness 1973, as *P.*
 347 *hemisphaerica* and *P. boldii*). This suggests that these two populations are
 348 reproductively isolated, and that divergent selection may be acting on these populations
 349 but *rbcL* and *cox1* gene sequences do not reflect this isolation (Nosil et al. 2009). These
 350 three scenarios show different evolutionary patterns even among closely related species
 351 (e.g. *P. villum* vs. *P. devoniensis*). Therefore, application of genetic distances in
 352 delineating species boundaries should be evaluated on a case by case basis. While these
 353 are very interesting issues from a taxonomic perspective, they are not the focus of this
 354 paper. From a phylogeographic point of view, whether these closely related
 355 monophyletic lineages are different species or not is of minor importance, because
 356 either way they share a common ancestor from which several genetic entities evolved.

357

358 *Phylogeographic patterns*

359 The paradox between expected dispersal limitation (Santelices 1990, Kilan and Gaines
 360 2003) and wide reported species distributions led us to hypothesize that such widely
 361 distributed species would either have strong phylogeographic structure or were spread
 362 by humans. Our results confirmed these hypotheses and exposed a third ~~options~~scenario,

363 where the morphologically defined species was in fact a complex of non-sister cryptic
364 species.

365 Three of the species ~~or groups of species form monophyletic lineages and~~ exhibit
366 genetic variability with clear phylogeographic structure in Australia, and the North and
367 South Atlantic (*Ophidocladus simpliciusculus*, *Lophosiphonia obscura* and
368 *Polysiphonia villum*). ~~Genetic divergences of sequences of these species from Australia,~~
369 ~~North and South Atlantic reflect geographical separation.~~ This result is not unexpected
370 considering that genetic divergence is promoted by the isolation among populations
371 separated by large geographic distances (Palumbi 1994). However, the observed genetic
372 divergence is relatively low (~~≤ up to~~ 0.9%) considering that Australia and the North and
373 South Atlantic ~~these regions~~ have been separated since about 80 My (Jordan et al. 2016).
374 Therefore, rather than this genetic divergence resulting from an 80 My old vicariant
375 evolution, long-distance dispersal processes acting on a common ancestor and
376 subsequent divergence into differentiated populations are invoked to explain the
377 observed patterns. Mechanisms responsible for this long-distance dispersal are obscure
378 considering that these species either occur in coastal lagoons/estuaries or on sand-
379 covered rocks where buoyant macroalgae that can act as rafts are rare (Airoldi 1998,
380 Díaz-Tapia et al. 2013a). Molecular data have provided evidence for long-distance
381 dispersal in other red algal species but mechanisms remain unknown (Zuccarello et al.
382 2002a, Fraser et al. 2013). The genetic separation among geographically distant lineages
383 may indicate that long-distance dispersal occurs at a low rate. Alternatively, density-
384 dependent processes are involved and once a population colonizes a new region it
385 prevents the establishment of latecomers (Waters et al. 2013). Furthermore, available
386 data for the three species mentioned above indicate different evolutionary histories
387 and/or dispersal paths. For instance, in *L. obscura* and *P. villum* the largest sequence

388 divergences are between Australian and Atlantic populations, whereas in *O.*
 389 *simpliciusculus* the Australian haplotype is relatively close to South African and
 390 European haplotypes but the divergence across the Atlantic (Brazil vs. Europe) is much
 391 larger.

392 Several species showed a diversity of haplotypes sharing the same region: the
 393 Pacific *Symphyocladia spinifera* and *S. dendroidea*, as well as the Atlantic *Polysiphonia*
 394 *devoniensis*. The origin of this diversity must be related to processes of isolation that led
 395 to genetic differentiation, followed by local dispersal events. As ~~in~~ for *Ophidocladus*
 396 *simpliciusculus*, *Lophosiphonia obscura* and *Polysiphonia villum*~~the examples~~
 397 ~~mentioned above~~, dispersal mechanisms for *S. spinifera* and *P. devoniensis* are
 398 unknown. In contrast, *S. dendroidea* has been reported growing on stranded holdfasts of
 399 the floating alga *Durvillaea antarctica* (Macaya et al. 2016, López et al. 2017, 2018),
 400 which could contribute to dispersal after genetic differentiation ~~influencing~~ influenced
 401 its genetic structure.

402 The disjunct distribution of a second group of species (*Polysiphonia devoniensis*
 403 and *Symphyocladia dendroidea*) can be explained by human-mediated introduction
 404 events. The human transport of species from native (donor) to introduction (recipient)
 405 regions causes the rapid expansion of species' distribution and alters natural
 406 phylogeographic patterns (Straub et al. 2016). The discovery of *P. devoniensis* in
 407 Victoria (Australia), exhibiting a single haplotype that is also present in Europe,
 408 suggests that this species has been introduced into this country from Europe, possibly
 409 Atlantic Spain or the NW Mediterranean. *Symphyocladia dendroidea* was recorded as
 410 an introduced species in the French Mediterranean in 2005 (Boudouresque and
 411 Verlaque 2008, as *P. tanakae*) and our recent discovery of the same haplotype in a
 412 marina in Atlantic Spain probably represents a secondary introduction and suggests that

the species is spreading in Europe via hull fouling. The presence of several genetically separated lineages of *S. dendroidea* in Pacific South America contrasts with the occurrence of a single haplotype in Japan, Australia and California. Japan and Australia have the same haplotype, suggesting that one or both populations could be introduced. Genetic diversity of seaweeds in the introduced regions is either similar or reduced relative to the native area (McIvor et al. 2001, Provan et al. 2008, Voisin et al. 2005, Geoffroy et al. 2016). The finding of diverse haplotypes in the introduced region is indicative of an introduction involving several haplotypes or multiple introductions, depending on the phylogeographic structure in the native area (McIvor et al. 2001, Voisin et al. 2005, Geoffroy et al. 2016). A single haplotype of both *S. dendroidea* and *P. devoniensis* has been detected in the areas where the introduction of these species is certain, suggesting that their introduction is the result of a single event in which a single haplotype was involved. However, much more complex scenarios could explain the observed patterns and a better understanding of the phylogeographic patterns in native and introduced areas would be needed to elucidate the introduction dynamics.

P. devoniensis in Australia is represented by only one haplotype, compared to eight in the North Atlantic, suggesting that the introduction could be the result of a single event in which a single haplotype was involved. *Symphocladia dendroidea* was recorded as an introduced species in the French Mediterranean in 2005 (as *P. tanakae*) and our recent discovery of the same haplotype in a marina in Atlantic Spain probably represents a secondary introduction and suggests that the species is spreading in Europe via hull fouling. The presence of several genetically separated lineages in Pacific South America contrasts with the occurrence of a single haplotype in Japan, Australia and California. Furthermore, Japan and Australia have the same haplotype, suggesting that one or both populations could be introduced.

Our study showed that in the regions where *S. dendroidea* (Europe) and *P. devoniensis* (Australia) are known to be introduced, each species is represented by a single *rbcL* haplotype. Genetic diversity of seaweeds in the introduced regions is either similar or reduced relative to the native area (McIvor et al. 2001, Provan et al. 2008, Voisin et al. 2005, Geoffroy et al. 2016). The finding of diverse haplotypes in the introduced region is indicative of an introduction involving several haplotypes or multiple introductions, depending on the phylogeographic structure in the native area (McIvor et al. 2001, Voisin et al. 2005, Geoffroy et al. 2016). *P. devoniensis* in Australia is represented by only one haplotype, compared to eight in the North Atlantic, suggesting that the introduction could be the result of a single event in which a single haplotype was involved. Likewise, only one haplotype was found in Europe for *S. dendroidea*, showing reduction of genetic diversity if South America were the native area, but this is uncertain and much more complex scenarios could explain the observed patterns. An alternative hypothesis is that South America is a centre of diversification of lineages and that two of them established naturally in other Pacific regions, where the genetic diversity of the *rbcL* gene remains low, and that it has been introduced in Europe from one of these locations. Thus, a better understanding of the phylogeographic patterns in native and introduced areas would be needed to elucidate the introduction dynamics.

The third group of species analyzed here involved species complexes of non-sister cryptic species (*Xiphosiphonia pennata* including *X. pinnulata* and *Symphyclocladia spinifera*; *S. dendroidea*; and *Herposiphonia tenella*) ~~in which specimens~~ morphologically identified as a single species were resolved as complexes of non-sister cryptic species. In both cases species found in the Atlantic and Pacific basins differ, but in addition several species were found with overlapping distributions in some regions of

each basin. Therefore, the distribution of these widely reported species is much narrower than previously thought. Cryptic algal species often involve a group of morphologically similar species that are genetically differentiated, but resolve as a monophyletic group (Zuccarello et al. 2002a, Won et al. 2009, Payo et al. 2013). However, examples of non-monophyletic cryptic “species” have also been documented in the red algae (Zuccarello et al. 2018). Morphological similarity among non-monophyletic groups of cryptic species can be explained by evolutionary convergence, morphological stasis or developmental constraints (Leliaert et al. 2014, Zuccarello et al. 2018). *X. pennata*, *S. spinifera* and *S. dendroidea* are placed in a tribe (Pterosiphonieae) with high morphological variation ranging from filiform to foliose species (Díaz-Tapia et al. 2017b). The body plan of both species is filiform, among the simplest observed in the tribe, and morphological stasis is a plausible explanation for their similarity. In the tribe Herposiphonieae all species are very similar in morphology, with limited differences in their body plans (Díaz-Tapia et al. 2017b) and the cryptic diversity in *Herposiphonia tenella* might result from morphological stasis or developmental constraints.

Understanding the processes underlying phylogeographic patterns requires the study of numerous specimens from across the entire distribution of the species. In this regard, we recognize important limitations in our work that prevent us from fully elucidating causes of the observed phylogeographic patterns, leading to some tentative conclusions about the potentially introduced status of some of the analysed populations. However, most of the species treated here are rare in all or part of their known distribution range so improving the datasets would be very difficult. For example, *Lophosiphonia obscura*, despite being widely reported, is very rare in the regions here studied: the sample from the UK used in this study is the first one collected since 1970

(Maggs and Hommersand 1993). In Spain, we found it only once in the Atlantic and once in the Mediterranean, and the species is here recorded for only the third time in Australia. Our work should thus be interpreted as one of the first attempts to understand phylogeographic patterns of widely distributed red algal species. Even though ~~some of the nuances of their~~ evolutionary history ~~remain unknown~~ is not well known, our analyses provide clear examples of 1) species with wide distributions and strong phylogeographic structure that reflects the geographical distances~~species complexes in which non-monophyletic cryptic diversity has been found~~; 2) species with a broad distribution that can be only explained by human-mediated transport; and 3) species complexes in which non-monophyletic cryptic diversity has been found~~species with wide distributions and strong phylogeographic structure that reflects the geographical distance~~. This study indicates that widely distributed species are the exception in red algae, except when they have been spread by humans.

Supplement S1. Taxonomic notes.

Lophosiphonia obscura, *Polysiphonia hemisphaerica* and *P. boldii*

The taxonomic history of *Lophosiphonia obscura* is complex (Silva et al. 1996, Díaz-Tapia and Bárbara 2013), involving several names that have been proposed in different regions. Among these names are *Polysiphonia hemisphaerica* from Scandinavia (Rueness 1971) and *P. boldii* from USA (Wynne and Edwards 1970). Rueness (1973) showed that male and female gametophytes of these two species successfully interbreed, producing carpospores from which tetrasporophytes germinate. However, the viability of tetraspores obtained from these tetrasporophytes was reduced. Thus, despite their high *cox1* similarity, *P. boldii* and *P. hemisphaerica* failed to produce fully fertile progeny and the taxonomic status of these two species remained unresolved (Rueness 1973, 2010). We obtained *rbcL* sequences for the three taxa and our phylogenetic analysis revealed that they form a clade, are closely related (tree not shown), and whether they should be considered a single species is unclear. For simplicity, we are including these three currently recognized taxonomic species under the heading “*Lophosiphonia obscura*” but a taxonomic revision is required to clarify their taxonomic status.

Polysiphonia villum

Polysiphonia villum was originally described based on Mexican material (Agardh 1863) and its taxonomic status with regard to the Australian *P. scopulorum* was questioned (Cribb 1956). Based on its morphology, Hollenberg (1968) proposed to retain *P. villum* as a variety of *P. scopulorum*. However, molecular data showed that material attributed to these two taxa represents two different, non-monophyletic, molecular entities (Huisman et al. 2017). Consequently, here we apply the name *P. villum* to the molecular entity that matches American specimens (Stuercke and Freshwater 2008) and differs from Australian specimens (Huisman et al. 2017). Assessment of the correspondence of both *P. scopulorum* and *P. villum* with their respective type material has not been studied.

Polysiphonia devoniensis and *P. kapraunii*

Polysiphonia devoniensis was originally described from southern England (Maggs and Hommersand 1993) and subsequently recorded at other locations in Atlantic Europe (Díaz-Tapia and Bárbara 2013). More recently, *P. kapraunii* was described from North Carolina (Stuercke and Freshwater 2010). Our phylogenetic analysis revealed that these two entities form a clade, are closely related (tree not shown), and whether they should be considered a single species is unclear.

Symphyocladia dendroidea

Symphyocladia dendroidea was originally described from Peru and subsequently recorded from other locations in Pacific America, Argentina and Namibia (Fig. 2c). More recently, *S. tanakae* was described from Japan (Uwai and Masuda 1999, as *Pterosiphonia tanakae*) and it was recorded as an introduced species in the Mediterranean (Verlaque et al. 2015). The synonymy between these two species was proposed based on similarity of sequence data from their type localities (Bustamante et al. 2016a).

Xiphosiphonia pennata, *X. pinnulata* and *Symphyocladia spinifera*

Xiphosiphonia pennata was widely reported on Atlantic and Pacific coasts (Fig. 2e, as *Pterosiphonia pennata*) and successive publications have unmasked cryptic diversity in this taxon, resolving a Pacific and two Atlantic species. Maggs and Hommersand (1993) noted that the smaller, less robust European forms of this species should be assigned to *X. pinnulata* (as *P. pinnulata*). This distinction was later supported by molecular data (Díaz-Tapia and Bárbara 2013). Kim et al. (2012) revealed that Korean specimens previously regarded as *X. pennata* represented a distinct molecular species compared to European specimens and *P. arenosa* was described. Recently, the synonymy of *P. arenosa* with *Symphyocladia spinifera* (as *P. spinifera*; type locality Peru) was proposed (Bustamante et al. 2016b). A taxonomic revision of the tribe Pterosiphonieae demonstrated that, despite the high morphological similarity among *X. pennata*, *X. pinnulata* and *S. spinifera*, they do not form a clade (Savoie and Saunders 2016). In fact, they are placed in two distinct lineages and accordingly, the Pacific entities *P. arenosa* and *P. spinifera* were transferred to the genus *Symphyocladia*, while the Atlantic entities *P. pennata* and *P. pinnulata* were placed in the new genus *Xiphosiphonia* (Savoie and Saunders 2016).

* Only one *rbc* L sequence of *Symphyocladia dendroidea* 2 was included in our phylogeny. However, six *rbc* L sequences and 22 *cox* 1 sequences were generated for this species (Savoie & Saunders 2016)
